**Introduction**

Gun violence and ballistic injuries are serious public health problems in the United States that are associated with substantial morbidity and often require orthopedic expertise in treatment. The incidence of firearm injuries has increased in recent years. An estimated 134,000 nonfatal firearm injuries occurred nationally in 2017, an increase of over 50% from two years prior according to the Centers for Disease Control and Prevention.\(^1\) The majority of these injuries occur in urban areas, like Philadelphia, which saw 2,266 shooting victims in 2020, nearly double the number from 2015.\(^2\) Firearm injuries continue to rise with 354 shooting victims from Jan 1\(^{st}\)-March 3\(^{rd}\) 2022.\(^3\) The violence predominantly affects males, those under the age of 35, and racial minorities. In Philadelphia, people of color comprised 95% of gunshot wound (GSW) victims in 2021.\(^2\) Therefore, proper treatment of GSW injuries is an important component of health equity. This article reviews basic management of GSW injuries along with specific insights obtained from working at a high-volume urban Level 1 Trauma Center.

**Guns, Ammo, and Ballistic Wounds**

Current firearms can be classified in three basic categories: shotguns, rifles, and handguns. Shotguns are smoothbore with limited range, firing either multiple pellets or a single projectile (slug). Wadding is used to separate the propellant from the projectiles. Rifles are long barreled with parallel spiraling grooves along the bore, called rifling, which gives ejected bullets rotational spin. With this stabilization, rifles can fire powerful ammunition with increased range and accuracy. Handguns may also have rifling along their barrels but are typically less than 30 cm in length.\(^4\) Handgun rounds are generally less powerful and less accurate. Exceptions to this rule, however, are increasingly relevant as rifle and handgun distinctions blur.

Bullets are typically lead alloy projectiles (Figure 1). Two key variations on a standard solid design include jacketed and partially jacketed bullets. Jacketed rounds are composed of a soft lead core encased in a harder metal alloy. Partially jacketed bullets, “hollow point,” have an exposed tip which allows the projectile to flatten and expand on impact. This transmits more force and leads to more significant and complex injuries. Ballistic wound character and severity are therefore heavily influenced by mechanism of injury as much as anatomic location. First, the kinetic energy (KE) of a bullet is greatly influenced by the projectiles speed (KE = \( \frac{1}{2} \times M \times V^2 \)). Conventional categorization relies on this characteristic in grouping injuries as either resulting from bullets at low-velocity (< 2,000 ft/s) or high-velocity (> 2,000 ft/s). However, actual energy transfer is an important
component of the injury. A bullet which comes to rest within
the body will transfer its entire KE after impact, compared
to the smaller fraction of a bullet which exits. Bullets create
a permanent cavity through the tissue though often not in
a straight path. Upon impact, the projectile experiences
increased yaw, the angle between bullet axis and its initial
trajectory, and after 15 degrees will begin to tumble. Bullet
trajectory is further altered by fragmentation or striking bone.
In high velocity injuries, tissues adjacent to the direction of
travel of the projectile will undergo a rapid radial expansion.
This expansion forms a temporary cavity with significant
damage to small blood vessels and peripheral nerves, and may
cause simple fractures.

**Acute management**

Death prior to arrival of first responders on scene is a major
driver of firearm mortality. Philadelphia has sought to reduce
prehospital time by allowing police to directly transport to
trauma centers. On arrival, patients are stabilized per ATLS
protocols. In the trauma bay at Penn Presbyterian, airway,
breathing, and circulation are rapidly assessed as the patient is
fully exposed. All penetrating wounds are then identified and
marked with taped paperclips (closed for anterior and open
for posterior) to assist in trajectory identification (Figure 2).
The presence of a single wound (or odd number) increases
suspicion for a retained bullet. Wounded areas are assessed
for pallor, gross contamination, joint effusions, exposed bones,
and compartment swelling. Vascular examination using ABI/
ABPIs are conducted in cases of poor perfusion or pulsatile
bleeding with CT angiography available for continued
concern. A neurologic exam documents baseline function.

Tetanus prophylaxis is given and, time permitting, wounds are
irrigated to remove gross debris, photographed, and dressed.
Standard radiographs are taken for assessment of possible fractures, retained bullets, and joint injuries. The fracture is
then reduced when necessary and splinted. Skeletal traction
is applied for fractures of the acetabulum, femur, or if there are
retained materials in the joint (Figure 3).

**Treatment Overview**

Low velocity GSW fractures can often be treated similar
to closed injuries with the goal of restoring function and
minimizing complication. Formal debridement is typically not
required, and patients are treated with simple wound care
and a short course of oral broad-spectrum antibiotics. Stable
fractures can be managed conservatively with appropriate
wound care. The ulna and tibia remain exceptions, with
increased rates of infection stemming from their relatively
subcutaneous position. These are treated as open fractures
with operative irrigation, debridement, stabilization, and soft
tissue coverage as needed. Exploration for soft tissue bullet
removal is not recommended due to the risk of damage to
surrounding structures. Symptomatic subcutaneous bullets,
however, should be removed.

High velocity GSW fractures require more complex
treatment emphasizing life and limb saving procedures.
Extensive soft tissue injury can include vital end organs which
require management by general trauma surgeons. In cases of
severe trauma, controlling bleeding is imperative to prevent
the lethal triad of hypothermia, coagulopathy, and acidosis.
Wound hemorrhage should be managed with direct pressure
using a sterile dressing (Figure 3), followed by neurovascular

retained ballistic fragments.
around the best antibiotic regiment for non-operatively treated GSW fractures. Not only is there no clear superiority between oral and intravenous antibiotics in recent meta-analysis, but also some studies show no significant difference in infection rates in GSW fractures treated with antibiotics versus those that are not treated with antibiotics. Furthermore, gram negative coverage is not necessary in operative or non-operative treated patients based on similar infection rates between first and third generation cephalosporins. At Penn, a single dose of first-generation cephalosporin is employed to reduce the risk of microbial resistance and avoid antibiotic side effects. High velocity GSW fractures are treated as open fractures and require early administration of antibiotics. First generation cephalosporin are employed for 48–72 hours (potentially longer in cases of serial debridement) with no additional requirement for enhanced gram negative coverage. In situations with significant bone loss, soft tissue injury, or both, antibiotic-impregnated polymethylmethacrylate (PMMA) beads can be added for dead space management and synergy with intravenous antibiotics.

Vascular Injuries

Vascular injury should be identified quickly as these patients are at risk of not only volume depletion but also associated nerve injury and infection. In lower extremity GSW injuries, ankle-brachial indexes should be obtained, where a ratio of < 0.9 necessitates further vascular assessment (e.g., vascular consult, CTA, MRA, angiography). In the event of vascular injury, proximal control should be obtained through either a tourniquet (distal injuries) or surgical vascular control (abdomen or pelvis). Surgical treatment includes shunting to restore blood flow, provisional or definitive bony stabilization,

vascular repair, and fasciotomies. GSW fractures with associated vascular injuries have a higher rate of infection and should be monitored closely.  

Nerve Injuries

Nerve injuries in GSW trauma should be identified early with a neurologic examination of the limb when able. A vascular injury should increase suspicion of a nerve injury because 71% of patients with an arterial injury will also have an associated nerve injury. However, a nerve impairment does not diagnose neurotmesis (laceration). Nerves in the vicinity of a high-velocity GSW may sustain significant intraneural damage, axonotmesis.

In cases of nerve laceration, the ends should be tagged and repaired if the wound is clean. Nerve conduction studies should be conducted only in a delayed fashion (usually three or more weeks from time of injury) to allow for Wallerian degeneration signs to appear. When patients show no signs of improvement three months after initial GSW injury, referral to a peripheral nerve specialist should be considered. Persistent neuropathic pain is often the result of severe scar tissue constriciting an otherwise intact nerve. Creation of a healthy tissue bed is essential to nerve recovery which may require soft tissue coverage procedures like local soft tissue rearrangement or fasciocutaneous free tissue flaps. Mixed motor and sensory nerves such as the common peroneal, ulnar, and median nerve tend to have worse outcomes.

Summary

Increasing gun violence in the United States has now brought ballistic injuries once exclusive to warfare to many civilian trauma centers. Management of GSW injuries is related to the amount of energy imparted to the receiving tissue. Life or limb threatening injuries are the priority of treatment which often require a multidisciplinary team effort (Figure 5). Low-velocity GSW fractures can be treated as closed injuries and often managed non-operatively according to standard fracture principles. Exceptions to this include injuries to the subcutaneous bones, like the ulna and tibia, and intra-articular retention. High-velocity GSW fractures require surgical irrigation, debridement, and fixation.
